Abstract

Examination of the oral cavity is an integral part of every clinical examination. The clinical presentation of various viral conditions is discussed in this article and will provide the family practitioner with an up to date guide to better diagnosis and management.

Introduction

Viral infections of the oral mucosa are frequently encountered in general practice. The clinical diagnosis of these lesions can sometimes be confusing due to similar clinical presentations. The clinical presentation, diagnosis and appropriate management of common viral infections of the oral mucosa are discussed.

Herpes simplex virus

Primary herpetic gingivostomatitis

The infection that accompanies primary herpetic gingivostomatitis is usually subclinical in early childhood and only a small percentage of patients develop an acute primary infection. This usually occurs in older children and consists of fever, malaise, headache, cervical lymphadenopathy and a vesiculo-ulcerative eruption on the peri-oral skin, vermilion or any intra-oral mucosal surface. The vesicles, which are 2 to 3 mm in diameter, rupture, leaving painful ulcers that heal without scarring after seven to ten days. The gingivae are swollen and reddish due to a general inflammation (see Figure 1). The virus then migrates to the trigeminal ganglion, where it remains latent. In more affluent countries with better living conditions and less overcrowding, many young adults do not acquire the infection during childhood. They are at risk of developing a symptomatic infection as an adult, usually presenting as a pharyngotonsillitis, with constitutional symptoms of fever, malaise and headaches. In the case of cervical lymphadenopathy, the vesicles and ulcers on the tonsils and posterior pharynx can resemble infectious mononucleosis or a streptococcal sore throat infection. Primary infection in an immunocompromised adult can be life threatening, with disseminated disease, or it may present with extensive non-healing oral ulceration.

Secondary herpes labialis

Around 15 to 30% of the community is affected by episodes of secondary herpes simplex lesions (herpes labialis). Common colds, influenza, fever, UV exposure, menstruation, emotional upset, stress and anxiety predispose the patient to recurrent infection, as these cause reactivation of the virus, which subsequently migrates along one of the sensory divisions of the trigeminal nerve. The lesions are most often seen at the mucocutaneous junction of the lip or peri-oral skin (see Figure 2). A burning sensation usually precedes the development of a small cluster of vesicles. These vesicles enlarge, coalesce, ulcerate and become crusted before healing within 10 days.

Diagnosis and management

The clinical features are usually sufficient to diagnose these conditions. The differential diagnosis of primary herpetic gingivostomatitis includes recurrent aphthous ulceration, which forms ulcers on non-keratinised oral mucosa without a vesicle phase.

Patients must be discouraged from touching the lesions.
in order to reduce the risk of spreading the infection to other sites. Systemic acyclovir may be used for immunocompromised individuals.\(^1\)

**Varicella-zoster virus**

Chickenpox (varicella) results from primary infection, while reactivation of the virus is known as herpes zoster (shingles). Intra-oral vesicles of varicella, when present, are seen on the tongue, buccal mucosa, gingival, palate and oropharynx. They generally are not very painful. Following the primary infection, the virus is transported via the sensory nerves to the dorsal spinal ganglia or trigeminal ganglion, where it remains latent.

A number of predisposing factors can lead to a recurrence of the infection in the tissue supplied by the sensory nerve. Conditions leading to herpes zoster are usually those that cause immunosuppression, such as cytotoxic drugs, radiation, internal malignancies, malnutrition, old age, and alcohol and substance abuse. Occasionally, dental manipulation in a localised area can lead to reoccurrence. The first signs of herpes zoster are pain and tenderness in the dermatome corresponding to the affected sensory ganglion. In the head and neck area, vesicles form on one side of the face or in the oral mucosa in one of the divisions of N. trigeminus. These unilateral vesicles form clusters with areas of surrounding erythema, ending abruptly in the midline (see Figure 3). The vesicles ulcerate and form pustules within three to four days. A crust lesion then forms, and healing takes place within seven to ten days. These lesions often heal with scarring and areas of hypo/hyperpigmentation may be seen. When the N. facialis and N. auditorius are involved (via the geniculate ganglion), facial paralysis, vesicles on the external ear, tinutitus, deafness and vertigo may follow. This is known as Ramsay-Hunt syndrome.\(^4\)

Spontaneous bone necrosis of the mandible, occurring during an acute attack of herpes zoster, has been seen in immunocompromised patients.\(^5\) The patients present with the unilateral vesicles of herpes zoster, with subsequent unilateral exfoliation of the teeth in the necrotic mandible (see Figure 4).

A residual complication of herpes zoster is post-herpetic neuralgia. It occurs in 10% of patients with herpes zoster and affects the trigeminal nerve, most commonly the ophthalmic division. There is persistent, unilateral pain in the affected area. A history of previous skin lesions and possible scarring may aid in the diagnosis. The pain is not paroxysmal, as is seen in trigeminal neuralgia, although it may be just as severe.

**Diagnosis and management**

The clinical picture is often distinctive. Herpes zoster may be confused with recurrent Herpes simplex virus infection. Herpes zoster has a longer duration, a more severe prodromal phase, unilateral vesicles and ulceration, with abrupt ending at the midline and post-herpetic neuralgia.

The treatment is supportive and symptomatic, with topical or systemic antipruritics and analgesics that do not contain aspirin. A high dose of oral acyclovir (800 mg five times daily for seven days) is recommended for treating both primary and recurrent infections in immunocompromised patients.\(^6\)

**Coxsackie virus**

**Herpangina**

Herpangina affects children, mainly during summer, and is characterised by a sudden onset of malaise, fever and a sore throat. Patients present with vesicles, ulcerations, and diffuse erythema on the soft palate, faucæ and tonsillar areas (see Figure 5). The systemic symptoms settle in two to three days and the ulcers heal in seven to ten days.

**Figure 3:** Herpes zoster, presenting with multiple ulcers on the palate. Note the abrupt ending of the ulcers at the midline (arrow).

**Figure 4:** Unilateral necrosis of the mandible (arrow) in an HIV-positive man with a CD4 count of less than 200.

**Figure 5:** Herpangina, presenting with multiple ulcers on the soft palate, uvula and fauces.

**Hand, foot and mouth disease**

Hand, foot and mouth disease is most commonly seen amongst children aged one to five years. In 75% of cases it presents with an eruption of vesicles on the palms of the hands and on the feet. Occasionally vesicles may also be found on the proximal extremities and buttocks. There are also vesicles in the anterior part of the mouth (see Figure 6). An associated low-grade fever and malaise are usually present.

**Diagnosis and management**

The clinical features of Coxsackie virus are distinctive. The distribution of the lesions of herpangina differentiates it from primary herpetic gingivostomatitis, which affects the gingivae, whereas herpangina is an oropharyngitis. The systemic symptoms differentiate it from recurrent aphthous ulceration. The vesicles also help to distinguish herpangina from streptococcal pharyngitis.

In the case of hand, foot and mouth disease, the cutaneous vesicles can resemble chickenpox; however, in chickenpox the vesicles usually start on the face and trunk and then spread to the extremities. Involvement of the palms and soles is rare in chickenpox infections. Oral lesions are also rare in chickenpox.

Herpangina and hand, foot and mouth disease are self-limiting, of short duration and need no treatment. Symptomatic treatment is indicated in very painful cases of herpangina, in which case non-aspirin antiinflammatory and topical anaesthetics can be used.

**Human papillomavirus**

**Focal epithelial hyperplasia (Heck’s disease)**

Heck’s disease presents with multiple asymptomatic, slightly elevated, mucosa-coloured, smooth-surfaced nodules that occur on the labial or buccal mucosa gingivae or tongue of children (see Figure 7). Individual lesions tend to be small (0.3 to 1 cm), but they frequently cluster and coalesce, giving the
mucosa a cobbled stone or fissured surface. Most lesions are found in children, although they occasionally can be found in older age groups. They usually regress spontaneously with age.

Squamous cell papilloma and verruca vulgaris
Squamous papilloma is a slow-growing, solitary, painless, cauliflower-like lesion with branched finger-like processes (see Figure 8). It can occur at any age, but is most commonly diagnosed in the age group 30 to 50 years. It may initially grow rapidly, but seldom grows beyond 5 mm in diameter. Although any site of the oral cavity may be affected, the tongue, lips and soft palate are common locations. The lesion will range from reddish to white, depending on the degree of surface keratinisation.

Verruca vulgaris is a very common childhood infection. Oral lesions usually arise from autoinoculation, most commonly on the labial mucosa, tongue and gingiva. It presents as a slow-growing, painless, exophytic lesion that consists of sharp, finger-like processes.

Condyloma acumminatum
Condyloma acumminatum is usually present on the genitals, although it may be found in the oral cavity. Oral lesions are predominantly transmitted through oral-genital sexual contact. It consists of multiple cauliflower-like lesions, some of which are larger than 0.5 cm. They may become as large as 3 cm in size. The most common intra-oral sites are the labial mucosa and the lingual frenum.

Diagnosis and management
No treatment is usually required for focal epithelial hyperplasia, as the nodules undergo spontaneous regression during puberty. Lesions that cause aesthetic problems or are chronically injured can be removed surgically.

It is often impossible to distinguish between verruca vulgaris and squamous cell papilloma of the oral mucosa. Excision of both lesions is the treatment of choice.

Condyloma acumminatum should not be confused with focal epithelial hyperplasia. It may be difficult to distinguish from squamous cell papilloma, which is usually single and not larger than 0.5 cm. Excision is the treatment of choice. The presence of these lesions in children should raise the possibility of sexual abuse, although on rare occasions they may be transmitted by non-sexual contact.7

Human immunodeficiency virus
Although no oral lesions are found as a direct result of HIV infection itself, a range of HIV-associated oral lesions, some with a viral aetiology, have been described.

Oral hairy leukoplaikia
This presents as a white, vertically corrugated, non-removable lesion on the lateral or ventral margin of the tongue (see Figure 10). The surface might be non-corrugated if it is seen on the inferior surface of the tongue or in the buccal mucosa. This lesion is caused by the Epstein-Barr virus and has no premalignant potential. It has also been reported in HIV-negative persons.
in association with immunosuppressive therapy. It must be differentiated from chronic hyperplastic candidiasis or leukoplakia (a potentially malignant lesion). A biopsy must be performed to establish a reliable diagnosis. Once the diagnosis has been made, no treatment for the lesion is necessary.

Kaposi’s sarcoma
Kaposi’s sarcoma is characterised by erythematous or violaceous plaque-like lesions that develop into tumorous growths over time (see Figure 11). These larger lesions may become ulcerated and painful and may interfere with function. Kaposi’s sarcoma is predominantly seen in the palate or on the attached gingivae, but can appear on other mucosal sites. It has been demonstrated that Kaposi’s sarcoma is caused by infection with human herpes virus 8. The clinical diagnosis should be confirmed by biopsy, as several other lesions may have similar clinical presentations. This is especially true for early lesions that may have similar clinical features as vascular malformations, bacillary angiomatosis and even well differentiated anaplastic sarcoma. A variety of treatment options are available varying from intralesional injection of chemotherapeutic or sclerosing agents to surgery or radiotherapy. Regression of Kaposi’s sarcoma has been reported in patients receiving combination antiretroviral therapy.

Figure 11: Kaposi’s sarcoma of the palate (arrows) in (A) the early plaque stage and in (B) the more advanced tumorous phase on the gingiva (arrows).

Conclusion
Examination of the oral cavity should routinely be performed as the oral mucosa is often the first site affected by viral infections. A thorough medical history together with a detailed examination will result in an accurate diagnosis for the majority of viral lesions affecting the oral cavity, resulting in appropriate patient care. Persistent lesions, especially if ulcerated, should be biopsied to exclude the possibility of a non-infective, more serious aetiology. Biopsies or other laboratory investigations should also be performed if a clinical diagnosis can not be established. This is especially true in the setting of HIV/AIDS that can influence the typical clinical features of viral infections.

ATROVENT® 20 HFA: The first CFC-free Ipratropium Bromide

Boehringer-Ingelheim is proud to announce the launch of the new ATROVENT® 20 HFA metered dose inhaler which will replace the existing ATROVENT® 40 inhaler once stocks are depleted.

The availability of ATROVENT® 20 HFA is in line with Boehringer-Ingelheim’s commitment to provide effective and affordable alternatives to CFC-containing inhalers.

ATROVENT® 20 HFA is indicated for the relief of symptoms associated with asthma and COPD. Each 20 µl metered dose (puff) contains 0.021 mg ipratropium bromide and it will be necessary to adjust the patient’s dosage accordingly.

Patients using ATROVENT® 20 HFA for the first time might notice that the taste is slightly different from that of the CFC-containing ATROVENT® 40 metered dose inhaler. This is due to the limited amount of alcohol needed to dissolve the active ingredients. Patients should be made aware of this when changing from one formulation to the other.

ATROVENT® 20 HFA’s introduction highlights Boehringer-Ingelheim’s commitment to provide high quality, research-based, affordable products to the healthcare market in South Africa.
